ABSTRACT

Origins of Gender Norms: Sibling Gender Composition and Women's Choice of Occupation and Partner*

I examine how one central aspect of the childhood family environment – sibling gender composition – affects women's gender conformity, measured through their choice of occupation and partner. Using Danish administrative data, I causally estimate the effect of having a second-born brother relative to a sister for first-born women. The results show that women with a brother acquire more traditional gender norms with negative consequences for their labor earnings. I provide evidence of increased gender-specialized parenting in families with mixed-sex children, suggesting a stronger transmission of traditional gender norms. Finally, I find indications of persistent effects to the next generation of girls.

1 Introduction

Across most OECD countries, women today attain more education than men and participate almost equally in the labor force (OECD, 2016; OECD, 2017). But why do women keep choosing fields of study that lead to substantially lower-paid occupations (Blau and Kahn, 2016)? Although the barriers to women’s participation in education and the labor force have been removed in an attempt to achieve gender equality, gender identity still plays an important role for gender differences in behavior and subsequently economic outcomes (Akerlof and Kranton, 2000; Bertrand, 2011; Goldin, 2014). To fully understand why women continue to behave in ways that lead to inferior labor market outcomes relative to those of men, we need to better understand the origins of—especially women’s—gender norms. In this study, I focus on the importance of one key aspect of the childhood family environment—sibling gender composition—for women’s socialization and the development of gender conformity.

The family constitutes an essential facet of a child’s socialization process. Parents act as important role models and transmit gender norms to their children (Farre and Vella, 2013; Fernández et al., 2004; Humlum et al., 2017; Johnston et al., 2013; Kleven et al., 2018). At the same time, siblings are close peers during childhood and often sustain long-lasting relationships throughout life (McHale et al., 2013). A child’s birth order in the sibship influences—for instance—educational attainment and the development of personality traits through social family interactions (Brenøe and Molitor, 2018; Black et al., 2005, 2017; Lehmann et al., 2016). Sibling gender composition might additionally have a crucial impact on how siblings interact with each other, as well as how parents interact with their children (McHale et al., 2003). For instance, parents might invest differently in their children depending on the children’s gender composition, which in turn could alter the intergenerational transmission of gender norms.

To examine how sibling gender composition affects the development of women’s gender conformity, I use high-quality administrative data for the universe of the Danish population from 1980 to 2016. With this comprehensive data set, I evaluate women’s gender identity through their revealed gender conformity in terms of their choice of occupation and partner from the age of 31 to 40 (proxied by the gender share in their own and their partner’s occupations, respectively). To provide causal estimates of the impact of sibling gender, I exploit the random assignment

of the second child's gender in families with a first-born daughter, conditional on the parents having a second child. The crux of my identification strategy is thus to compare the choices for first-born women with a second-born brother to those with a second-born sister. While sibling gender composition has a small impact on family size, I show that family size is not a confounding factor for the effect of sibling gender composition on women's gender conformity. This empirical approach distinguishes itself from previous studies on sibling gender composition, which generally include all siblings in both the measure of sibling gender composition and the estimation sample.¹ However, considering all siblings is problematic, given that the final sibling gender composition in a sibship is endogenous. Therefore, studying the effects of older siblings' gender on younger siblings' outcomes might lead to selection bias. For example, if parents decide to have a second child depending on their first child's gender and if parents with different gender preferences raise their children differently, the estimated effects would be biased. By focusing on the second-born child's gender, I avoid selection bias, as parents do not know the gender of their unborn child when deciding to have another child.

The setting for this study is ideal, as Denmark has been one of the front runners in terms of gender equality for decades. Women from the cohorts of study (1962–1975) attain slightly more education compared with men² and importantly, labor force participation is not gendered. The fact that labor market participation and family formation are not associated with gender identity is a unique (and very essential) feature for the empirical analysis, thereby removing concerns regarding selection into having an observation on choice of occupation, choice of partner, and the outcomes of a first-born child. Nonetheless, pronounced gender differences in

¹E.g. Amin (2009); Anelli and Peri (2014); Bauer and Gang (2001); Butcher and Case (1994); Conley (2000); Cools and Patacchini (2017); Cyron et al. (2017); Hauser and Kuo (1998); Kaestner (1997); Oguzoglu and Ozbeklik (2016); Rao and Chatterjee (2017). The only exceptions to such a strategy are Cronqvist et al. (2015) and Peter et al. (2015), investigating the effect of a co-twin's gender on financial risk taking, education, earnings, and family formation. Moreover, Gielen et al. (2016) employ a difference-in-differences strategy to estimate the effect of having a male twin on earnings, although their interest lies in whether exposure to prenatal testosterone (rather than sibling gender composition per se) has an effect on earnings. Cools and Patacchini (2017) and Rao and Chatterjee (2017) both provide a robustness check of their estimates on wages in which they only consider the sex of a next younger sibling.

²This is a fortunate feature, as previous studies on sibling gender composition have been concerned with the potential role of differential parental monetary investment in daughters when also having sons, as parents in more traditional societies tend to favor boys. In Denmark, on average, parents do not favor one gender over the other (Andersson et al., 2006). Therefore, sibling gender is not associated with financial constraints.

occupational choice still persist. For example, women are still heavily underrepresented in occupations within Science, Technology, Engineering, and Mathematics (STEM). Therefore, in many ways, the setting is comparable to the conditions faced by women in other developed countries today.

My results show that having a second-born brother relative to a sister increases first-born women's gender conformity: women with a brother work in more female-dominated occupations during their thirties and choose more traditional partners. In particular, women with a brother are 7.4 percent less likely to work within STEM. In other words, having a brother reduces women's probability of participating in traditionally male-dominated occupations. STEM is one important example of such occupations due to its potential consequences for the individual woman and society, given the higher wage returns to STEM fields and the need for a talented STEM workforce to sustain long-run economic growth (Altonji et al., 2015; Kirkeboen et al., 2016; Peri et al., 2015). Consistent with the fact that male-dominated occupations are typically better paid, I show that women with a brother earn less than those with a sister. I provide evidence that differences in labor market participation and family formation cannot explain the effects on occupational choice or labor earnings. While the main analysis concerns the development of women's gender identity, I also briefly present the results from a similar analysis for men (Section 6). In line with the findings for women, the results suggest that having an opposite-sex sibling enhances men's gender conformity.

The effect of sibling gender on women's gender conformity propagates through life and is already visible when considering their educational choice. While sibling gender has no effect on educational attainment or achievement, women with a brother complete less male-dominated educations. As an example, having a brother reduces women's probability of completing any field-specific STEM education by 11.3 percent. This effect on women falling out of STEM fields is already present in their first educational choice after compulsory schooling at the age of 16. The key finding that women with a brother acquire more gender-typed human capital further motivates analyzing whether the effects persist into the human capital formation of the next generation. Remarkably, the results show that daughters' comparative advantage in language over math in school is larger for those with a more gender-conforming mother, i.e. for daughters of mothers with a brother relative to daughters of mothers with a sister. Thus, I find striking evidence of very

persistent long-run consequences of women's childhood family environment.

Why does sibling gender affect the development of women's gender identity? The effect of having a brother could go through either child-parent and/or child-sibling interactions.³ I provide compelling evidence in favor of the former channel by showing that parents of mixed-sex children invest their time more gender-specifically in their first-born daughter compared with parents of same-sex children. The results from heterogeneity analyses further indicate that the effect of having a brother is strongest for women from more traditional families. These findings are consistent with the argument—similar to the one put forward in the same-sex education literature (Booth et al., 2013; Schneeweis and Zweimüller, 2012)—that having an opposite-sex sibling increases girls' exposure to gender-stereotypical behavior and thereby increases their inclination to acquire more traditional gender norms. In support of this argument, Cools and Patacchini (2017) and Rao and Chatterjee (2017) provide some indications that women with brothers hold more traditional gender attitudes than those without brothers.

My focus on the social environment and the origins of gender norms is consonant with recent studies tracing gender gaps in educational outcomes to factors such as teacher stereotypes, the gender of school peers and teachers, as well as parental and sibling role models.⁴ For instance, one strand of the literature shows that gender stereotypes in the school environment affect the gender gap in math test scores.⁵ However, fewer studies trace effects into outcomes with consequences for economic well-being in adulthood—such as the field of education, working decisions, and earnings—partly due to limited data availability. Nonetheless, some exceptions exist; for instance, Olivetti et al. (2018) show that having more female peers with working mothers during adolescence increases young women's probability of working and Kleven et al. (2018) show that women's child penalty on wages is largest for those from more traditional families. The literature on sibling gender composition is small and has predominantly been concerned with educa-

³The impact of having a brother on gender identity could also theoretically be due to changes in ability and parental resource constraints. However, I rule this out by showing that sibling gender does not affect school performance or attainment.

⁴See e.g. Anelli and Peri (2014, 2016); Bottia et al. (2015); Brenøe and Lundberg (2017); Brenøe and Zölitz (2018); Carrell et al. (2010); Cheng et al. (2017); Zölitz and Feld (2017); Humlum et al. (2017); Joensen and Nielsen (2017); Johnston et al. (2013); Oguzoglu and Ozbeklik (2016).

⁵Several studies find that having a gender-stereotypical teacher increases the math test score gap, mainly by reducing girls' performance (Alan et al., 2017; Carlana, 2017; Lavy and Sand, 2015; Lavy and Megalokonomou, 2017).

tional attainment, while a couple of more recent papers focus on wages.⁶ The evidence on educational attainment is mixed overall, while studies on wages reach a more consistent finding that both male and female wages are negatively associated with having an opposite-sex sibling, similar to my findings.

This paper makes five important contributions to the existing literature. First, I provide a comprehensive analysis of how sibling gender composition causally affects the development of women’s gender identity, using two novel measures of gender conformity (choice of occupation and partner). Second, the large sample size and administratively-reported occupations provide precisely-estimated effects on the gender conformity of women’s occupational choice.⁷ Third, to the best of my knowledge, I am the first to consider the gender conformity of the choice of women’s partner, which is again only possible due to the rich data set, as I am able to identify all partners and their occupations without relying on self-reports. Fourth, I document lasting effects on the next generation of girls, thereby stressing the persistence of gender norms. Fifth, I conduct a large quantitative analysis of how sibling gender composition affects child-parent interactions, thereby providing a detailed picture of an important channel through which the effects on gender identity operate.

2 Empirical Strategy

The aim is to estimate the causal effect of sibling gender composition on the formation of women’s gender identity. However, simply comparing women from families with different gender compositions would not provide valid estimates of the causal effect of sibling gender composition due to selection. The final gender composition in a family is endogenous, as parents decide whether or not to have more children after each child birth and thus when knowing their current children’s gender composition. If parents’ decision to have a second child depends on the first child’s gender and if such gender preferences also affect how parents

⁶See the references in Footnote 1. However, small sample sizes pose a general problem, often resulting in quite imprecise estimates and potential biases.

⁷This is in contrast to the few existing studies that have attempted to consider occupational outcomes, such as an occupational prestige score and binary indicators for occupational groups (Cools and Patacchini, 2017; Rao and Chatterjee, 2017). However, their sample sizes (< 5,000) are too small to allow for any clear conclusions, although the estimates of the signs are generally consistent with my main findings.

raise their children, it is not possible to estimate the causal effect of “current” (first-born) children’s gender on “future” (second-born) children’s outcomes because not all “future” children are born.⁸

To estimate the causal effect of sibling gender composition, I focus on the random assignment of the second-born child’s gender. Because parents do not know the gender of a subsequent child when they make the decision to progress to the next parity, I *can* causally estimate the effect of a “future” child’s gender on “current” children’s outcomes. Thus, I leverage the random assignment of the second child’s gender in families with a first-born daughter, conditional on having a second child. In other words, I compare first-born women who have a second-born brother with first-born women who have a second-born sister. Thereby, the identifying assumption is that conditional on the first child’s gender and conditional on having a second child, the sex of the second child is random.

The empirical specification for the main analysis is:

$$Y_i^{First-Born} = \alpha_0 + \alpha_1 Brother_i^{Second-Born} + X_i' \delta + v_i, \quad (1)$$

where $Y_i^{First-Born}$ measures woman i ’s (who is first-born) gender conformity. The estimate of interest is α_1 , representing the effect of having a second-born brother. X_i is a vector of fixed effects for birth municipality, year-by-month of birth, spacing in months to the second-born sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education.⁹ v_i is the error term.¹⁰

As this strategy only relies on the random assignment of the second child’s sex, parents can respond to the gender composition of their first two children in terms of subsequent fertility. Consistent with the literature exploiting sibling sex composition as an instrument for family size (e.g. Angrist and Evans (1998)), Appendix Table A1 shows that for the main sample of the analysis (described in Section 3) having two mixed-sex children reduces family size by 0.07 children on average. Therefore, family size could potentially mediate some of the effect of having a second-born brother if family size has an independent impact on gender identity. Existing studies find that family size does not affect educational attainment in Is-

⁸Appendix A.1 shows the selection bias problem more formally and discusses other reasons for selection bias aside from parental gender preferences.

⁹If the parent does not have a field-specific education, I use their field of occupation.

¹⁰I do not cluster the standard errors; however, the results do not change if I do so.

rael or Norway, using twins as an instrument for family size (Angrist et al., 2010; Black et al., 2005). In Appendix A.2.1, I replicate this finding in the Danish context and show that family size also does not affect the different measures of gender conformity. Appendix A.2.2 provides additional tests of the sensitivity of the findings, which further lend support to the conclusion that the results are robust to family size. Based on this wide battery of tests, family size does not seem to be an important confounder of the effect of sibling gender.

3 Data

3.1 Data and Sample Selection

I use Danish administrative data for the total population from 1980 to 2016. One central feature of this data set compared to most previous studies on sibling gender composition is that I can link all children to their parents and siblings. Thus, I observe parents' complete fertility history and thereby correctly measure the sibling gender composition. Furthermore, I have information on parents' date of birth, length, type, and field of education, labor market attachment, and occupation. For the children, I annually observe labor market outcomes, educational enrollment and completion, fertility, cohabitation, and marital status. Finally, I observe the school performance of the children's children.

I restrict the sample to women born between 1962 and 1975 to study the choice of occupation and partner when these women are in their thirties. Moreover, I only include first-born women, who are the first child to both the mother and father. I exclude immigrants¹¹ I only consider individuals who have at least one full sibling (same mother and father) born less than four years apart and who survives the first year of life, I exclude families in which either the first or second child is a twin, and finally I exclude those few women who die before the age of 40 or do not live in Denmark at any time between the age of 31 and 40, when the main outcome variables are measured.¹² I refer to this sample of first-born women as the *main*

¹¹For first-generation immigrants, I do not necessarily have complete sibling or parental information. Second-generation immigrants would have represented approximately one percent of the sample, reason for which I decided to exclude them to have a more homogeneous sample. However, including second-generation immigrants does not change the results.

¹²Sibling gender composition does not affect attrition due to these restrictions.

Main sample (first-born women born 1962–1975 with a second-born biological sibling born within four years apart). Panel A shows the average and standard deviation of family background characteristics for first-born women with a second-born sister [Columns (1) and (2)] and brother [Columns (3) and (4)]. Column (5) reports the *p*-values from *t*-tests of significance between the averages of the two groups of women. All binary variables (variables measuring shares) are multiplied by 100 to express percent (percentage points). Panel B tests whether the control variables included in X_i in Equation (1) can predict having a second-born brother. *F*-test of joint significance of all control variables.

sample.

Table 1 provides descriptive statistics on the childhood family environment for the main sample by the gender of the second-born sibling. As expected, these women come from families with similar predetermined family characteristics regardless of sibling gender. On average, spacing to the younger sibling is 2.5 years, mothers are 22.9 years at birth and have 10.9 years of education, while fathers are 25.7 years and have 11.8 years of education. When it comes to characteristics that the parents can manipulate after realizing the gender composition of their first two children, we see that those with two daughters are more likely to have more children, as discussed in Section 2. Meanwhile, the probability of having both parents working equally¹³ during childhood or living with both biological parents at the age of 17 does not differ by sibling gender composition. However, among those not living with both parents at the age of 17, we see a clear difference in the family living arrangement: divorced parents with mixed-sex children are more likely to live with their same-sex child only.

To provide support for the identifying assumption that sibling gender is random, Column (5) in Panel A tests whether the background characteristics differ by the gender of the second-born sibling. Considering the predetermined characteristics, only father's age at birth differs marginally between the two groups.¹⁴ Panel B shows statistics from a balancing test, testing whether the demographic characteristics included in X_i in equation (1) can predict sibling gender. More precisely, it reports the F -test of joint significance of all of the covariates in a regression where the outcome is an indicator for having a second-born brother. The F -test strongly rejects joint significance. Thus, this balancing test supports the identifying assumption that the younger sibling's gender is random, conditional on the first child's gender and conditional on having a second child.¹⁵

¹³I define this as the tertile of families in which the parents' division of labor until the child turns 19 years is most equal. More precisely, fathers in this group work at most 62 percent of total parental labor supply. I observe parents' labor supply through a mandated pension scheme (ATP), in which employers contribute for each employee based on the number of hours worked.

¹⁴To account for this small baseline difference, I flexibly control for parental age among a wide range of other fixed effects in the analysis.

¹⁵The graphs in Appendix Figure A1 illustrate the estimates from an event study of the effect of having a second-born son on a variety of parental socio-economic characteristics. The gender composition of children does not affect parental cohabitation, marital status, length of education, employment, or annual labor earnings before or around the birth of their first child.

3.2 Outcome Variables

The three main outcome variables evaluate the degree of women’s gender conformity. The first outcome reflects how gender-typed the individual woman’s occupational choice is. More precisely, I construct this variable as the natural logarithm of the average male share in the woman’s four-digit occupation codes observed between the age of 31 and 40.¹⁶ The second outcome measures the share of years between the age of 31 and 40 during which the woman works in a high-skilled STEM occupation. The third outcome quantifies how traditional the woman’s choice of partner is. This variable measures the natural logarithm of the female share in the partner’s occupation.¹⁷ Table 2 provides descriptive statistics on the outcome variables for the main sample of women by sibling gender and for a sample of men with similar selection criteria as for the main sample, for comparison. We observe a strong degree of gender segregation in occupational choice. While women on average have 33 percent men in their occupation, this number is 72 percent for men. Similarly, women’s partners have on average 28 percent women in their occupation, compared with 66 percent for men’s partners. Moreover, men are three times more likely than women to work within STEM.

To study potential causes and consequences of occupational choice, I further consider educational and labor market outcomes. I examine labor market outcomes from the age of 18 to 40 in terms of the labor earnings percentile by age and cohort, work experience, and unemployment history. The earnings percentile provides a standardized measure of relative income that includes individuals with zero earnings, is comparable across cohorts and ages, and is constructed based on the total population. At the age of 40, women have an average earnings percentile of 49, corresponding to a mean labor income of 320,000 DKK (43,000 EUR). While women only earn 70 percent of men, men and women participate almost equally in the labor market: by the age of 40, women (men) have 14 (16) years of work experience and 1.8 (1.2) years of unemployment. Similarly, these cohorts of women

¹⁶I use the Danish version of International Standard Classification of Occupations (DISCO), which I observe from 1991 to 2013.

¹⁷I define the partner as the mode person with whom the woman cohabits or is married between the age of 31 and 41. Sibling gender has no impact on women’s probability of having an observation on the partner’s occupation (not reported). I consider the logarithm of the male share in the woman’s own occupation and the logarithm of the female share in her partner’s occupation because these measures best approximate a normal distribution rather than considering the logarithm of the male share in both persons’ occupations.

Table 2
Descriptive Statistics on Outcome Variables for Sample of First-Born Women by
Gender of Second-Born Sibling (and First-Born Men for Comparison)

	Women				Men	
	Sister		Brother		Sister/Brother	
	Mean (1)	SD (2)	Mean (3)	SD (4)	Mean (5)	SD (6)

Main sample (first-born women born 1962–1975 with a second-born biological sibling born within four years apart); the sample of men corresponds to the one of women with the exact same sample selection criteria. Columns (1) and (3) show the average outcome variables for first-born women with a second-born sister and brother, respectively, while Column (5) shows the average for first-born men regardless of the second-born's gender. All binary variables (variables measuring shares) are multiplied by 100 to express percent (percentage points).

and men attain an almost equal length of education: by the age of 30, women have on average completed 13.3 years of education and men have completed 13.2 years. Consistent with the differences in occupational choice, the male share in the highest completed degree is much lower for women (36 percent) than for men (66 percent) and women are much less likely to enroll in and complete any field-specific STEM education.¹⁸

Furthermore, I examine whether sibling gender affects family formation through the age of 41. This aspect of women's life might reflect a certain degree of gender-conformity and might also influence labor market outcomes (Bertrand, 2011). First, I consider the share of years between the age of 18 and 41 during which the woman cohabits without being married (henceforth *cohabit*) and is married, respectively. Second, I consider the probability of having any children, the number of children, and age at first child birth conditional on having any children. Although having a partner (and being married) and having children might reflect a greater degree of gender-stereotypical behavior, this is not inevitably the case (Bertrand et al., 2016); instead, cohabitation could reflect non-traditional behavior, given that marriage is the tradition. Moreover, the vast majority (89 percent) of women have at least one child and most of those having children have exactly two. Therefore, gender identity may not necessarily influence family formation.

Finally, the last group of outcomes concerns the school performance of the next generation. For this, I consider the outcomes of the first-born child and split the sample by the child's gender.¹⁹ I examine the externally-graded grade point average (GPA) from the grade 9 written language (Danish) and math exams. Both measures are standardized with mean zero and standard deviation (SD) one by exam year for the entire student population. Generally, girls perform much better (0.45 SD) than boys in languages, while boys perform slightly better (0.10 SD) than girls in math. Therefore, languages may be perceived as more feminine and math more masculine. Thus, if mothers' gender identity transmits to their children (daughters), we might observe a widening in the gap between language and

¹⁸See Appendix A.3 for details on the educational outcomes and the educational system in Denmark with emphasis on STEM education.

¹⁹Given that child gender is independent of the gender of the mother's sibling, this split does not create any bias. Nonetheless, sibling gender might affect the mother's gender preference for her own children and thereby her subsequent fertility choices. Therefore, I only consider women's first-born children. I do not observe any selection into having an observation on a first-born child's outcomes.

math performance. Given previous findings suggesting that mothers influence their daughters more than sons and vice versa for fathers (Brenøe and Lundberg, 2017; Brenøe and Epper, 2018; Humlum et al., 2017), we would mainly expect to observe an effect of the gender of the mother’s sibling on daughter’s and not on son’s performance.

4 Results

4.1 Gender Identity: Choice of Occupation and Partner

Table 3 shows the main results on the impact of sibling gender on women’s choice of occupation and partner, with different control versions. The models in Column (1) show the raw means between first-born women with a second-born sister and those with a second-born brother, while Column (2) includes basic demographic controls. Column (3), the preferred model, further controls for parental education. Finally, Column (4) flexibly adds controls for family size and the sex of potential third- and fourth-born siblings.²⁰ As family size is an outcome of sibling gender composition, the latter control version might bias the estimates. However, this control version works as a robustness check of the results, as family size might also be considered a confounding variable. Regardless of the covariates included, the estimates across the different control versions are almost identical, supporting the assumption that sibling gender is random and illustrating that family size is not a principal mediator of the effect of sibling gender (as discussed in more detail in Appendix A.2). Therefore, the rest of this paper proceeds by presenting the results, using the preferred control version in Column (3).

Overall, the results show that having a second-born brother relative to a sister enhances women’s gender identity. First-born women with a second-born brother work in occupations with 1.22 percent fewer men compared to first-born women with a second-born sister. Note that this difference in occupational choice is observed well into these women’s labor market careers during their thirties (as an average from the age of 31 to 40). Consistent with this, having a brother also reduces women’s probability of working within STEM by 0.38 percentage points, corresponding to a decrease of 7.35 percent relative to the mean for women with a

²⁰The estimates are identical when not controlling for third- and fourth-born siblings’ gender.

All estimates are multiplied by 100 to express effects in percentage/log-points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Main sample (first-born women born 1962–1975 with a second-born biological sibling born within four years apart). Each panel column presents estimates from separate regressions. *Basic controls* include fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, and paternal age at birth. For the own occupation outcomes, basic controls also include dummies for the number of years observed in the income registry from the age of 31–40 and the number of years observed with a valid occupation code from the age of 31–40. For partner's occupation, basic controls also include dummies for the partner's number of occupational observations and age at first and last observation. *Parental education* controls include fixed effects for maternal level-by-field of education and paternal level-by-field of education. *Family size* controls include dummies for the number of biological siblings and dummies for the number of children that the mother and father potentially have, respectively, from later relationships, and the gender of potential third- and fourth-born siblings. The occupational outcomes of the first-born women are measured as a mean from the age of 31–40. The occupational outcome of the partner is measured mainly at the ages of 31–45 for the partner with whom the woman lived for most years from the age of 31–41.

Figure 1
 Distributional Effects of Sibling Gender on Choice of Occupation and Partner

(a) Log(Male Share in Own Occupation)

(b) Log(Female Share in Partner's Occupation)

All estimates are multiplied by 100 to express effects in log points. The whiskers represent the 95 percent confidence interval. Main sample (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart). All estimates come from separate quantile regressions. All models control for quadratic spacing to the second-born sibling, mother's and father's cubed age at birth, and absorb fixed effects for year of birth, indicators for missing parental age information, and a constant. The models in Graph (a) further control for dummies indicating the number of occupational observations and the models in Graph (b) control for the partner's number of occupational observations and age at first and last observation.

sister. Consequently, the results clearly show that having a brother induces women to exhibit more traditional choices of occupation. In other words, they are less

prone to opt into traditionally male-dominated occupations, of which STEM is one relevant example.

Moreover, sibling gender has a significant impact on the choice of partner in terms of the degree of how gender-typed his occupation is. Having a brother rather than a sister induces women to choose a partner who works in more male-dominated occupations. On average, women with a brother have a partner working in occupations with 1.88 percent fewer women than women with a sister. Not reported, having a brother increases the difference in the male share between the woman's own and her partner's occupations by 0.80 percentage points. Additionally, as a test of the robustness of the main measures of gender conformity, Appendix Table A5 considers two alternative measures. Strikingly, having a brother also increases the partner's relative earnings in the couple and the age from the woman to the partner. These results demonstrate a powerful effect of having a brother not only on women's choice of gender-stereotypical occupations and partners but also on other aspects of their gender-conforming behavior.

Figure 1 considers whether the effects differ across the different parts of the distribution, by presenting the results from quantile regressions. For both the male share in the woman's own occupation and the female share in the partner's occupation, the estimates are not statistically significantly different from each other from the 10th to the 90th percentiles. Nonetheless, for both measures, the estimates indicate strongest effects at the lower part of the distributions. At the 10th percentile, the estimated effects of having a brother relative to a sister are approximately twice the magnitude of those seen in Table 3. This suggests that women who are most strongly affected by having a brother are those who are more traditional than the average, potentially representing those from more traditional families.

If the effect of sibling gender at least partly goes through the way in which parents treat their children, we might observe some heterogeneity in the effect of having a brother by parental characteristics.²¹ Panel A in Table 4 includes an interaction term between sibling gender and an indicator for having parents working (close to) equally during childhood. Remarkably, the effect of having a brother on occupational choice disappears for women coming from more gender-equal families. This suggests that women with more gender-stereotypical parents drive the effect of sibling gender on the probability of choosing more female-dominated oc-

²¹As seen in Table 1, these parental characteristics do not differ by sibling gender composition.

All estimates are multiplied by 100 to express effects in percentage/log-points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Main sample (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart). Each panel column presents estimates from separate regressions. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. Columns (1) and (2) also include dummies for the number of years observed in the income registry from the age of 31–40 and the number of years observed with a valid occupation code from the age of 31–40. Column (3) also includes dummies for the partner's number of occupational observations and age at first and last observation. The occupational outcomes of the first-born women are measured as a mean from the age of 31–40. The occupational outcome of the partner is measured mainly at the ages of 31–45 for the partner with whom the woman lived most years from the age of 31–41. *Equal* indicates the tertile of families in which the parents' division of labor until the child turns 19 years is most equal.

cupations. Moreover, the results in Panel B suggest that the effect of having a brother is strongest for those women with more traditional parents in terms of their educational field. The effects seem to be largest in magnitude for those with a mother who has an academic education within care or administration and for those with a father who has an academic education within STEM.

Furthermore, the effect of having a brother is the largest for those with at least one highly educated parent (≥ 12 years of education) for occupational choice. In most cases, a highly educated parent will also imply having a parent with human capital that is traditionally associated with his or her own gender. For instance, most mothers with a long education are within care and administration (e.g. nurse, secretary, and office work) and most fathers are within STEM. Therefore, these results again support the previous findings that the effect of having a brother is strongest for those with more gender-stereotypical parents. Notably, the results also show that women with both parents having less education do not experience an effect of sibling gender. This suggests that the effect is not due to resource constraints, which has been put forward as a relevant mechanism in the sibling gender composition literature on educational attainment (Amin, 2009; Butcher and Case, 1994). Although the estimates are more imprecisely estimated for the other two outcomes, they are qualitatively consistent with the findings for the male share in the woman's occupation.

Expanding the sample to include women with up to eight years to their second-born sibling shows that sibling gender does not have an impact for those with long spacing to their sibling [Appendix Figure A2]. However, the estimated effects by spacing are not statistically significantly different from each other, probably due to the small fraction of children with long spacing to their second-born sibling. This finding that individuals with long spacing to their younger sibling do not experience an effect of sibling gender might indicate the importance of sibling interactions. However, it could also be because parents with children spaced far apart treat the first-born daughter similarly regardless of the younger sibling's gender.

In sum, these heterogeneities indicate that the effect of having a brother is strongest for women from more traditional families. In turn, this suggests that differences in child-parent interactions are important for the effects of sibling gender composition on the formation of women's gender identity. *Ceteris paribus*, we would expect that parents with more gender-stereotypical human capital would

reinforce gender specialization to a stronger extent than those parents with less gender-specific human capital (Humlum et al., 2017). Additionally, we would expect that spending more time with the mother than with the father would influence the child more in the direction of the mother's (female) rather than the father's (male) interests. Therefore, the results are consistent with the hypothesis that parents of mixed-sex children invest more time in their same-sex child than parents of same-sex children; Section 5 elaborates more thoroughly on this.

4.2 Labor Market Outcomes

As female-dominated occupations typically pay lower wages, an important consequence of the results on occupational choice might be reflected in lower labor earnings. To study this, I conduct an event study of the effect of having a brother on women's earnings percentile from the age of 18 to 40, with the age of 18 as the base, controlling for individual fixed effects. Note that sibling gender has a tight zero impact on earnings at the age of 18 (not reported). Once women enter the labor market,²² we observe a negative effect of having a brother on the earnings percentile in the order of 0.5 percentile [Graph (a), Figure 2].²³ Such a negative impact on earnings might be driven by differences in labor market participation rather than, or in addition to, occupational choice. Nevertheless, this is not the case, as Graphs (b) and (c) in Figure 2 illustrate that sibling gender does not affect women's cumulated work experience or cumulated length of unemployment. These findings of no effect on labor market participation (in terms of hours worked and unemployment) stress that labor market participation is not gendered in Denmark.

The finding of a negative consequence for earnings is unsurprising given the previous results regarding lesser participation in more male-dominated and STEM occupations. Similarly, Cools and Patacchini (2017) show that women in the U.S. with any brother earn less around the age of 30. Rao and Chatterjee (2017) do not find a significant effect of sibling gender composition on women's earnings among slightly older cohorts in the U.S., although their estimate of the effect of having

²²Using Danish data, Brenøe and Lundberg (2017) show that almost everybody will have finished their education around the age of 30.

²³Appendix Figure A3 demonstrates that the picture is similar when considering the earnings level and the natural logarithm of earnings instead.

Figure 2
Effect of Sibling Gender on Labor Market Outcomes Age 18–40

(a) Earnings Percentile

(b) Work Experience

(c) Unemployment

Main sample (first-born women born in 1962–1975 with a younger biological sibling born within four years apart). The whiskers represent the 95 percent confidence interval. All graphs illustrate the estimates from an event study of the effect of having a second-born brother, where the age of 18 forms the base. All models absorb time-specific fixed effects and individual fixed effects. *Earnings Percentile* measures the labor earnings percentile by age and cohort. *Work Experience* measures the cumulated lifetime work experience in months. *Unemployment* measures the cumulated lifetime unemployment in months.

a next younger male sibling indicates a negative impact. By contrast, studying a sample of female twins born in the first half of the last century, Peter et al. (2015) do not find an impact of having a co-twin brother on earnings. Moreover, both Cools and Patacchini (2017) and Rao and Chatterjee (2017) do not find significant effects of sibling gender composition on the type of occupation. This might be due to some

important empirical limitations (as the sign of their estimates broadly support my findings) because these studies rely on much smaller sample sizes, self-reported measures of occupation, and their methodological approach (i.e. the inclusion of all siblings in the measure of sibling gender composition and the inclusion of all birth orders in the sample).

4.3 Education and Family Formation

Another reason for the lower earnings could be due to differences in the accumulation of human capital. I do not find any evidence of an impact of sibling gender on educational attainment or school performance [Columns (2) and (3) in Panel A, Table 5].²⁴ Likewise, Cyron et al. (2017) does not find an effect of sibling gender on girls' cognitive or non-cognitive skills in first grade in the U.S.²⁵ Thus, sibling gender does not seem to affect differences in ability or (financial constraints in terms of) access to education. Consequently, these results demonstrate that sibling gender composition does not affect educational achievement or attainment, supporting an interpretation that changes in interests or identity are the channels of the effects of sibling gender on occupational choice. By contrast, the only existing study with causal estimates of sibling gender on educational attainment finds that having a male co-twin increases women's length of education (Peter et al., 2015). However, their sample might not be comparable with the more general population of singletons and for later birth cohorts.

While sibling gender does not affect overall educational attainment, the effect of sibling gender on occupational choice is closely mirrored in field of education by the age of 30. Having a brother reduces the share of men in the highest completed field-by-level of education by 1.36 percent.²⁶ Similarly, women with a brother rel-

²⁴Not reported, sibling gender does not affect the probability of having an observation on high school GPA or the probability of enrolling or completing different levels of education. Appendix Table A6 further shows that there is no effect on different types of ability, measured through grade 9 language and math written exam GPA. Appendix Figure A4 further illustrates the distributions of the three GPA measures by sibling gender composition. Given that the differences by sibling gender are extremely small, distributional effects do not seem to be important.

²⁵Similarly, I do not find any effect of sibling gender on personality traits [Big Five, growth mindset, trust, hedonism] or mental health [Strength and Difficulties Questionnaire (SDQ)] (not reported), based on the DALSC sample introduced in Section 5.

²⁶Despite major changes in society over time, the effect of sibling gender on the male share in the highest completed education by the age of 30 does not differ systematically by decade of birth when including cohorts born through 1986 (not reported). This is consistent with the finding by

Table 5
Effect of Sibling Gender on Education and Family Formation

	(1)	(2)	(3)	(4)	(5)
Panel A: Education by age 30					
	Log(Male Share)	Length (months)	High School GPA	STEM Enrollment	STEM Completion
Second-Born Brother	-1.36*** (0.53)	-0.12 (0.15)	-0.01 (0.01)	-0.63*** (0.17)	-0.57*** (0.13)
Observations	103,541	103,562	47,588	103,769	103,769
Panel B: Family Formation by age 41					
	Cohabit 18–41	Married 18–41	Has Any Children	# of Children	Age at First Birth
Second-Born Brother	-0.80*** (0.13)	-0.12 (0.17)	-0.20 (0.20)	0.00 (0.01)	0.07** (0.03)
Observations	103,769	103,769	103,769	103,769	91,953

Estimates in Columns (1), (4), and (5) in Panel A and Columns (1), (2), and (3) in Panel B are multiplied by 100 to express effects in percentage/log-points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Main sample (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart). Each panel column presents estimates from separate regressions. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. The educational outcome models, except for high school GPA, further control for age at last observation in the education registry. *Log(Male Share)* measures the natural logarithm of the share of men in the highest completed education (narrow field-by-level) by the age of 30. *Length* measures the length of the highest completed education in months by the age of 30. *High School GPA* measures final GPA from the academic high school and is standardized by track and year of graduation for the total population with mean zero and standard deviation of one. *STEM Enrollment* indicates whether the woman has ever enrolled in a field-specific STEM education at the age of 16–27. *STEM Completion* indicates whether the woman has ever completed a field-specific STEM education by the age of 30. *Cohabit* measures the share of years aged 18–41 during which the woman has cohabited with a partner without being married. *Married* measures the share of years aged 18–41 during which the woman has been married. *Has Any Children* indicates whether the woman has at least one child by the age of 41. *# of Children* measures the number of children the woman has by age 41. *Age at First Childbirth* measures the age at the woman’s first child birth in years, conditional on having any children.

ative to those with a sister are respectively 7.6 and 11.3 percent less likely to ever enroll in and complete any field-specific STEM education. Appendix Table A6 further shows that the effect is already present in the type of first educational enrollment after compulsory education and that it is seen for STEM degree completion at different levels of education. Thus, having a brother pushes women out of traditionally male-dominated fields as early as the age of 16 and it is seen in both the field of education as well as occupation.

The magnitude of the effects are comparable with previous studies examining the impact of various aspects of the social environment in school on study choice (Bottia et al., 2015; Carrell et al., 2010; Schneeweis and Zweimüller, 2012; Fischer, 2017). Moreover, the results are broadly comparable with other studies examining correlations between sibling gender composition and field of college major (Anelli and Peri, 2014; Oguzoglu and Ozbeklik, 2016). Appendix Table A11 displays the associations between the gender of a first-born sibling and second-born women's gender identity, indicating similar but less robust correlations compared with the main results. These results are also closer to those in Anelli and Peri (2014), who do not find a significant association for women's enrollment in high-earnings college majors (although the magnitude of their estimate is relatively large). This stresses the importance of rigorously considering selection bias when the aim is to evaluate the causal effect of sibling gender.

In addition to differences in occupational and educational choice, one potential explanation for the negative effects on earnings might be differences in family formation. On the one hand, due to the acquisition of more traditional gender norms, one might expect women with a brother to marry earlier, have children earlier, and have more children than women with a sister. However, such a conjecture implicitly requires that being married and having children is an important aspect of women's gender conformity. This might very well not be the case in a modern setting in which women do not face a conclusive choice between having a family and a career (Bertrand et al., 2016; Goldin and Katz, 2002). For instance, the cohorts of women under study have all had access to contraceptives, abortion, various family leave policies, and infant child-care options.²⁷ On the other hand,

Haines et al. (2016) that gender stereotypes have not changed over the last three decades in the U.S.

²⁷Oral contraceptives (the pill) have been on the Danish market since 1966. All women have had free access to abortion since 1973 in Denmark.

women with a younger sister might experience more competition in terms of being the first among the two who marries and has children, as men (i.e. brothers) on average are older when they start their family formation. These two opposing forces might explain why I essentially do not find any effect of sibling gender on various aspects of family formation [Panel B in Table 5], consistent with the findings in Peter et al. (2015).

In terms of family formation, the results only suggest a small effect on cohabitation. Women with a brother cohabit 3.0 percent fewer years than those with a sister between the age of 18 and 41. This could in fact be due to more traditional gender norms, as more traditional women might want to wait longer before moving together with a partner before marriage.²⁸ Sibling gender has no effect on the probability of being married [Column (2)], age of first marriage, the probability of divorce or age at first divorce (the latter three not reported). Thus, the only difference between women with a brother and those with a sister is that the former move together with a partner before marriage slightly later. This might explain the small positive (though negligible) effect on age at first child birth. Overall, sibling gender has no effect on the fertility rate through the age of 41, i.e. close to complete realized fertility. Therefore, the effects of sibling gender on family formation are not a likely mediator of the effects on earnings. In turn, this supports an interpretation of a causal positive effect of having a more male-dominated education and working in more male-dominated occupations on female earnings.

4.4 Persistent Effects to the Next Generation (of Girls)

So far, I have documented that the childhood family environment affects the development of women's gender conformity. Having a brother influences the family environment to such a degree that women choose more female-dominated occupations and more gender-conforming partners. An intriguing question is whether this effect on gender identity is sufficiently strong to affect the next generation—and in particular the next generation of girls. To investigate this, I examine the school performance of these women's first-born daughters and sons separately. If having a more gender-stereotypical mother (and father) affects the next generation, we

²⁸The majority of these cohorts cohabit and have children before marriage. Ninety-one percent of the women in the sample have cohabited for at least one year before the year they get married and 53 percent get married in the year of their first child birth or later.

All estimates are multiplied by 100 to express effects in percent of a standard deviation. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. First-born children to the main sample (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart) born in 1986–1999. All models absorb fixed effects for the mother's birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. The Grade 9 GPA measures come from the written exam at the end of grade 9 in respectively Danish and Math and are standardized by year of graduation for the total population with mean zero and standard deviation of one.

would expect daughters to perform better in languages and/or worse in math. For boys, the prediction is less clear, as the literature typically finds that boys are less sensitive to the social environment (Bottia et al., 2015; Carrell et al., 2010; Fischer, 2017). Remarkably, Table 6 shows that daughters whose mother's second-born sibling is male relative to female perform 2.37 percent of a standard deviation better in languages, while there is no effect on their math performance or for sons. Thus, daughters' difference in language and math ability is larger for those with a more gender-conforming mother. This increase in girls' absolute advantage in languages over math might in turn predict more traditional choices of field of education. Notably, I find evidence of very persistent long-run consequences of women's childhood family environment.

5 Gender-Specific Parenting as a Relevant Mechanism

5.1 Literature Background

The previous section documents that sibling gender affects women's acquisition of traditional gender norms and that the impact seems to be strongest among women

from more gender-stereotypical families. This subsection draws on the literature to identify relevant mechanisms behind these findings, while the subsequent subsection provides some empirical evidence. Overall, I consider changes in identity to be the main channel of the impacts on choice of occupation and partner, as the previous analysis does not suggest that differences in educational attainment, ability, labor force participation, family size, or resource constraints are important or driving mechanisms. Consistent with the same-sex education literature (Booth et al., 2014; Schneeweis and Zweimüller, 2012), the overarching argument is that girls with a brother are more exposed to gender-stereotypical behavior in the family and therefore they are more inclined to acquire traditional gender norms. In this context, gender-stereotypical behavior could become more salient through changes in the nature of either child-sibling and/or child-parent interactions, including parental investments.²⁹

First, parents might interact differently with their children depending on the gender composition in terms of the quantity, quality, and content of time spent together. Assuming that both parents spend at least some time with their children, a traditional household specialization model suggests that parents gender-specialize their investment in children when having mixed-sex children if mothers are more productive in creating female human capital and fathers are more effective in creating male human capital (Becker, 1973). Parents might also derive more utility from spending time with a same- compared to an opposite-sex child due to the type of activities undertaken with the child. In both cases, parents of mixed-sex children would gender-specialize to a greater extent than those of same-sex children.

McHale et al. (2003) suggest that because parents of mixed-sex children have the opportunity to gender-differentiate their parenting, children with opposite gender siblings might have the strongest explicit gender stereotypes. Endendijk et al. (2013) find some evidence that fathers with mixed-sex children exhibit stronger gender-stereotypical attitudes than those with same-sex children. Previous research has further documented that overall mothers talk more in general and more about interests and attitudes with daughters than sons (Maccoby, 1990; Leaper et al., 1998; Noller and Callan, 1990). By contrast, fathers talk more and spend more time with sons than daughters and have a greater emotional attachment to

²⁹Appendix A.4 provides a brief overview of alternative mechanisms discussed in previous papers on sibling gender composition. These mechanisms cannot be the dominating explanations, as they are not compatible with the empirical findings.

sons (Bonke and Esping-Andersen, 2009; Morgan et al., 1988; Noller and Callan, 1990). These different pieces of evidence thus suggest that parents of mixed-sex children gender-specialize their parenting more and thereby expose their children more to gender-stereotypical behavior than parents of same-sex children, which in turn might result in a stronger transmission of gender norms in families with mixed-sex children.

Second, first-born girls might interact differently with their second-born sibling depending on the siblings' gender. In particular, having a brother might make girls more aware of "appropriate" female behavior and thereby induce them to develop more gender-stereotypical attitudes. For instance, Booth and Nolen (2012) show that girls attending same-sex schools are no more risk averse than boys, while girls attending mixed-sex schools are significantly more risk averse. Women are generally less competitive than men and this gender difference in competitiveness seems to be stronger in mixed-sex relative to same-sex environments (Bertrand, 2011; Niederle and Vesterlund, 2011). Traditionally male-dominated (STEM) fields are further considered more competitive (Buser et al., 2014). Therefore, having a brother instead of a sister might change women's degree of competitiveness and thereby their preferences for working in competitive environments. Having a brother might thereby induce women to develop more gender-stereotypical attitudes due to a greater awareness of gender through sibling interactions. This in turn could be reinforced by parents' increased gender specialization. In particular, previous studies have documented that women with brothers behave more family-centered and express more traditional attitudes towards gender roles (Cools and Patacchini, 2017; Rao and Chatterjee, 2017).

Thus, differences in child-parent interactions and in particular increased gender specialization in families with mixed-sex children is a particularly important mechanism for the observed effect of sibling gender on women's formation of gender identity, which I am able to test for empirically. In the remainder of this section, I explore this mechanism by investigating the impact of sibling gender composition on parental time investment. More precisely, in the daily child-parent interactions, we might observe that parents of mixed-sex children invest more quality time in their same-sex child. This could explain the heterogeneity in the effect of sibling gender documented in Table 4. Furthermore, in the case of parental divorce, we might expect that children from mixed-sex child families would be more likely to

live with their same-sex parent compared to same-sex children due to a stronger degree of gender-specialized parenting. Consequently, it is common for these predictions that a parent of mixed-sex children influences his or her same-sex child more than a parent of same-sex children.

5.2 Empirical Evidence on Gender-Specific Parenting

To investigate whether sibling gender composition affects child-parent interactions, I draw on the Danish Longitudinal Survey of Children (DALSC).³⁰ The survey comprises five waves of children born in 1995 and is unique due to its very detailed information on parental time use and family socio-economic characteristics. For this analysis, I select first-born girls who have a second-born sibling born within four calendar years apart.³¹ At the age of 7 and 11, both parents report how often they undertake different types of activities together with their first-born daughter. I construct an index on parental time investment, using principal component analysis, and standardize it with a mean of zero and standard deviation of one [Appendix Table A7]. I define quality time as playing with the child, helping with homework, doing out-of-school activities, reading/singing, and going on an excursion.

Columns (1) to (4) in Table 7 provide the results on parental time investment by each parent for the two ages, separately. Mothers of a first-born daughter and a second-born son invest *more* time in their first-born daughter at both ages compared to mothers with two daughters. The increase is in the magnitude of 14–17 percent of a standard deviation. By contrast, fathers invest 20–23 percent of a standard deviation *less* time in their first-born daughter when having mixed-sex children. This reduction in total paternal time investment is driven by reduced time spent helping with homework and reading for the daughter [Appendix Table A8]. This finding indicates that girls with a younger brother receive less qualified help with homework in traditionally male-dominated subjects, which might prevent them from growing interests in these fields. Furthermore, this effect on father-daughter

³⁰The study was designed by researchers from SFI, the Danish National Centre for Social Research, in collaboration with other research institutions. The survey includes 6,011 randomly-sampled children born between September and October 1995 to a mother with Danish citizenship and comprises five waves (1996, 1999, 2003, 2007, and 2011).

³¹I only observe the year of birth of siblings and therefore do not have more precise information on spacing.

Table 7
Effect of Sibling Gender on Parental Time Investment in First-Born Daughters
and Family Structure

	Parental Time Investment (Born 1995)				Family Structure (Born 1962–75)

Main Sample						
All					✓	
Divorced						✓

Standard errors in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. DALSC sample: Columns (1) through (4). Main sample: Columns (5) and (6). Estimates for the main sample are multiplied by 100 to express effects in percentage points. Each column represents the results from separate regressions. All models using the DALSC sample control for (quadratic) mother and father's age and fixed effects for spacing to the younger sibling in years, parental marital status in 1996, parents having been together for at least 5 years in 1996, region of birth, maternal level of education, paternal level of education, and family income level in 1995. Both models using the main sample absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, paternal level-by-field of education, and age at observation of family structure. *Parental time investment* is constructed using principal component analysis based on reports on how often each parent undertakes certain quality-time activities (playing, doing homework, doing out-of-school activities, reading/singing, going on an excursion) together with the child on a weekly basis and is standardized with a mean of zero and standard deviation of one; see Appendix Table A7. *Main Sample All* includes everybody who lives with at least one biological parent, while *Main Sample Divorced* excludes those living with both biological parents. *Lives w Both Parents* indicates that the first-born daughter lives with both biological parents at the age of 17. *Lives w Mother & Sib w Father* indicates that the first-born daughter lives with her mother and the second-born child lives with the father at the age of 17.

interactions translates into a substantially worse relationship between fathers and their first-born daughters when the second-born child is male relative to female [Appendix Table A9]. Overall, girls receive the same amount of time investment regardless of their younger sibling's gender. These results clearly show that first-born girls with a second-born brother experience more gendered parenting relative to those with a younger sister.³²

Ideally, I would have had similarly detailed data on parental inputs for the main sample. However, such information is not observed in the administrative registries. Instead, I observe all children's family structure at the age of 17.³³ Sibling gender composition does not alter the probability of living with both biological parents [Column (5) in Table 7]. In the case of parental divorce or separation (henceforth *divorce*), the living arrangement between parents and children in the main sample might additionally shed light on child-parent interactions in terms of splitting parents' time. If parents of mixed-sex children gender-specialize more than those of same-sex children, we would expect that divorced families with mixed-sex children would be more likely than families with same-sex children to have a living arrangement in which the first-born daughter lives with her mother and the second-born child lives with the father.

Conditional on living in a divorced family, the results show a pattern consistent with the prediction [Column (6)]. First-born daughters with a second-born brother are 5.30 percentage points (115 percent) more likely to live with their mother while their younger sibling lives with the father. These results consequently show a strong effect on the living arrangement among non-traditional families, thereby lending support to the previous findings (based on the much smaller DALSC sample) on more gender-specific parenting and time investment in families with mixed-sex children. In conclusion, these findings support the hypothesis that parents of mixed-sex children gender-specialize their parenting more than those of same-sex children, thereby strengthening the transmission of traditional gender-specific in-

³²For first-born boys, the overall picture is similar (not reported). Note, I cannot distinguish between whether this increase in gender specialization is driven by changes in demand (children) or supply (parents). Having a brother might cause the daughter to demand more maternal and less paternal time. However, the results clearly show that parents respond to sibling gender, which is the relevant margin, as any policy aiming to reduce the transmission of gender norms would most likely need to address parents and not children as young as 7 years.

³³I observe the family structure on January 1st each year and use the observation for the year when the person turns 18 years or the last year in which the child lives with at least one biological parent.

terests.³⁴

6 First-Born Men and their Second-Born Sisters

The main analysis investigates the effect of sibling gender on the origins of women's gender identity. This section briefly presents a corresponding analysis for men. However, I do not consider men's choice of partner or the school performance of their first-born children, because I find that sibling gender affects men's family formation in terms of both having a partner and having any children [Panel B in Appendix Table A13]: put differently, considering those outcomes might create selection issues and potentially bias the estimates. I construct the sample of men with identical selection criteria as for the main sample of women and conduct an identical analysis with the same variable definitions and controls.

Overall, the results for first-born men suggest that having a second-born sister relative to a second-born brother enhances men's gender identity [Appendix Table A12]. Men with a sister have a slightly higher (borderline significant) share of men in their occupation and they are 0.51 percentage points (3.7 percent) more likely to work within STEM.³⁵ Importantly, however, having a sister also reduces the probability of working in managerial occupations by 0.44 percentage points (6.6 percent).³⁶ This decrease in the likelihood of working in (high-paid) managerial positions may help to explain why men with a sister experience lower labor earnings than men with a brother [Appendix Figure A5]. At the same time, men with a sister accumulate less work experience at the end of their thirties relative to those with a brother, while there is no effect on lifetime unemployment by the age of 40. Thus, men with a sister appear somewhat less successful in the labor market.

Similar to my findings, previous studies find negative effects of having sisters relative to brothers on men's earnings in Sweden and the U.S. (Peter et al., 2015; Rao and Chatterjee, 2017). Rao and Chatterjee (2017) show that in the U.S. brothers

³⁴Not reported, considering heterogeneity by living in a traditional family for occupational choice shows that the effect is strongest for women from divorced families. This is consistent with increased gender specialization in these families. However, there is no significant heterogeneity by family structure for working in STEM occupations or choice of partner.

³⁵The results are comparable when considering a binary indicator for having ever worked in STEM from the age of 31 to 40 (not reported).

³⁶Not reported, I find a tight zero effect of sibling gender on women's probability of working in managerial occupations (the estimated effect is 0.04 percentage points ($se = 0.07$)).

help each other more in job search than mixed-sex siblings, which could help to explain the negative effect on earnings and be a mechanism counteracting our ability to observe men's gender conformity through occupational choice. Moreover, Peter et al. (2015) discuss competition between brothers as an important channel of the positive effect of having a brother on earnings. Brothers might compete with each other to a much greater extent than mixed-sex siblings, both because men are more competitive than women and because having a same-sex sibling might change the reference point of competition (Butcher and Case, 1994; Conley, 2000). Joensen and Nielsen (2017) show that especially brother pairs influence each other in terms of educational choice. Panel A in Appendix Table A13 shows that having a sister increases men's probability of ever enrolling in any field-specific STEM (traditionally heavily male-dominated) program, supporting a change in their gender identity. However, the effect does not persist into actual degree completion, which again may suggest that having a sister reduces competitive behavior, making them strive—and ultimately—achieve less. Besides the effect on STEM enrollment, sibling gender does not influence men's educational attainment or achievement.

Like Peter et al. (2015), I also find that having a sister negatively affects men's family formation. Men with a sister cohabit and are married fewer years from the age of 18 to 41. Furthermore, having a sister reduces men's probability of having any children and their number of children. These findings could reflect less competitive behavior among men with a sister relative to those with a brother not only in the labor market but also in the marriage market. Thus, despite finding indications of similar effects of having an opposite-sex sibling on men's development of gender norms as for women, competition might play a similarly or more important role in terms of how men fare in the labor and marriage markets.

7 Conclusion

This study documents that the childhood family environment has a long-run impact on women's gender identity, with persistent effects to the next generation of girls. The results show that having a second-born brother relative to a sister increases first-born women's gender conformity (in terms of their choice of occupation and partner, the relative earnings between the woman and her partner, as well as the age difference to her partner). I further show that having a brother

negatively affects labor earnings. This is most likely driven by the effect on occupational choice, as sibling gender does not affect educational attainment, labor market participation or family formation. I provide compelling evidence that changes in child-parent interactions—and in particular increased gender-specialized parenting in families with mixed-sex children—play an important role for the changes in gender identity. This suggests that the transmission of traditional gender norms is stronger in families with mixed-sex children. Finally, I show that the increased gender conformity among women with a brother persists into the next generation of girls, as indicated by an increase in daughters' comparative advantage in language over math performance in school. Consequently, I find evidence of very persistent long-run consequences of women's childhood family environment.

To eliminate gender inequality caused by gender-conforming behavior, my findings imply that policy-makers need to focus on the formation of gender identity among girls in the childhood family environment. I show that having a brother already affects girls' study choices in a more gender-stereotypical direction at the end of compulsory schooling. This stresses that girls' development of gender identity by adolescence has important consequences for their later-life educational and labor market outcomes. As my mechanism analysis suggests, the family—representing a central aspect of the social environment during childhood—influences the formation of women's gender identity. Therefore, if society wants to give boys and girls the same opportunities at the time when they enter the labor market in adulthood, policy-makers need to focus on how to counteract gender-stereotypical human capital investments. Specifically, interventions would need to counteract the transmission of gender norms across generations and thereby the development of gender-stereotypical behaviors, attitudes, and preferences.

A Appendix

A.1 The Selection Bias Problem

To show the selection bias problem more formally, I here follow Peter et al. (2015). Assume a latent outcome $Y_i^* = \alpha + \beta G_i^{old} + X_i' \gamma + \epsilon_i$, where G_i^{old} is the gender of the older sibling and X_i is a vector of observable exogenous characteristics. ϵ_i contains other relevant unobservable variables, such as parental gender preferences denoted by P_i , and $E[\epsilon_i] = 0$. The bias arises due to the latent nature of Y_i^* , as we only observe the outcome if child i is born. In other words, $Y_i = Y_i^*$ if the child is born ($S_i = 1$) and Y_i is missing if the child is not born ($S_i = 0$). The selection depends on both parental preferences and the older child's gender, $S_i = f(P_i, G_i^{old})$. We can only estimate the effect for the sample of children who are born which gives the expected value of Y_i :

$$\begin{aligned} E[Y_i | S_i = 1, G_i^{old}, X_i] &= \alpha + \beta G_i^{old} + \gamma X_i + E[\epsilon_i | S_i = 1, G_i^{old}, X_i] \\ &= \alpha + \beta G_i^{old} + \gamma X_i + E[\epsilon_i | f(P_i, G_i^{old}) = 1, G_i^{old}, X_i]. \end{aligned} \quad (2)$$

As long as selection depends on the first child's gender and parental preferences affect the way in which parents raise their children $E[\epsilon_i | f(P_i, G_i^{old}) = 1, G_i^{old} = 1, X_i] \neq E[\epsilon_i | f(P_i, G_i^{old}) = 1, G_i^{old} = 0, X_i]$. This implies that the estimate of the older sibling's gender is biased.

A selection problem could also arise in the absence of parental gender preferences. Assume that first-born children have n normally-distributed traits, such as how easy the child is to take care of and how well it behaves. Suppose parents only want a second child if their first child has a value of each trait above a certain threshold. The threshold for or the distribution of each trait could be gender-specific. In both cases, parents who progress to the next parity would, on average, have different types of first-born children depending on the child's gender. For instance, if boys and girls have the same distribution of how well they behave but parents require girls to behave better than boys to have a second child, second-born children would, on average, have a better behaving older sibling if they have a sister compared to a brother. In this example, the estimated effect of the older sibling's gender on the younger child's outcomes might thus be due to the older sibling's behavior rather than due to his or her gender.

A.2 Family Size

Parents in developed countries are more likely to have a third child if their first two children are of same compared to mixed gender (Angrist and Evans, 1998; Angrist et al., 2010; Black et al., 2005). Appendix Table A1 shows that this is also the case in the main sample of the analysis. First-born women with a second-born brother are 13.2 percent less likely to have at least two siblings relative to those with a sister. The rest of this appendix examines whether family size has an independent effect on gender conformity and studies rigorously the robustness of the main results to family size.

Table A1
Effect of Sibling Gender on Parental Realized Fertility

	# of Siblings (1)	≥ 2 Siblings (2)	≥ 3 Siblings (3)
Second-Born Brother	-0.07*** (0.01)	-5.26*** (0.28)	-1.33*** (0.16)
Observations		103,769	
Average	1.6	37.2	7.7

Estimates for the outcomes ≥ 2 Siblings and ≥ 3 Siblings are multiplied by 100 to express effects in percentage points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Main sample (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart). Each column presents estimates from separate regressions. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. # of Siblings measures the total number of siblings the individual has, including full and half siblings. $\geq 2(3)$ Siblings takes the value of one if the person has at least two (three) full siblings and zero otherwise.

A.2.1 Does Family Size affect Gender Conformity?

Black et al. (2005) use twins as an instrument for family size to show that family size does not affect educational attainment, using Norwegian registry data; Angrist et al. (2010) find the same for Israel. However, they only consider length of schooling and not gender identity. Consistent with their findings and employing a similar strategy in the Danish context, in this supplementary analysis I show that family size does not affect educational attainment or the measures of gender conformity used in the main analysis.

Table A2

The Effect of Family Size on Gender Conformity using Twins as Instrument

	First Stage	Second Stage				
		Choice of Occ and Partner			Education	
	# of Siblings	Log(Male Share in own Occ)	Works in STEM	Log(Female Share in Partner's Occ)	Log(Male Share in Edu)	Length (months)
	(1)	(2)	(3)	(4)	(5)	(6)
Twins at 2 nd parity	0.71*** (0.02)					
# of Siblings		3.82 (3.35)	0.70 (0.82)	-1.85 (4.84)	-1.33 (3.78)	0.27 (1.06)
F-statistic of IV	1020.11					
Prob>F	< 0.001					
Observations	104,780	104,780	104,780	95,977	104,552	104,573
Effect×-0.07		-0.27	-0.05	0.13	0.09	-0.02

All second stage estimates (except *Length of Education*) are multiplied by 100 to express effects in percentage/log points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Main sample including twin siblings born at second parity (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart). Each column presents estimates from separate regressions. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. *# of Siblings* measures the total number of siblings the individual has, including full and half siblings. Columns (2) and (3) also include dummies for the number of years observed in the income registry from the age of 31–40 and the number of years observed with a valid occupation code from the age of 31–40. Column (4) also includes dummies for the partner's number of occupational observations and age at first and last observation. The occupational outcomes of the first-born women are measured as mean from the age of 31–40. The occupational outcome of the partner is measured mainly at the ages of 31–45 for the partner with whom the woman lived for most years from the age of 31–41. The effects are multiplied by -0.07 (*Effect×-0.07*), as it is the magnitude of the effect of having a brother on the number of siblings.

I use a sample with similar sample restrictions as for the main sample (see Subsection 3.1), with the exception that I include first-born singleton children who have younger twin siblings born at the second parity.³⁷ The instrument for family size is having twins at the second parity. Column (1) in Appendix Table A2 shows that the instrument is strong and relevant; see Angrist et al. (2010) and Black et al. (2005) for a discussion of the validity of the instrument.

Columns (2) to (6) show the second stage results. Similar to the findings for Norway and Israel, family size does not affect the length of highest completed education by the age of 30, neither does it significantly affect the woman's occupational choice, her choice of partner or her type of education. The last row in the table scales the estimates by -0.07 (i.e. the effect of having a second-born brother on the total number of siblings). This statistic ($Effect \times 0.07$) illustrates that if family size (despite not having any statistically significant effect on the outcomes) would mediate some of the effect of sibling gender, any potential bias would be tiny.

A.2.2 Robustness to Family Size

As shown in Appendix Tables A1 and A2, sibling gender composition affects family size but family size does not affect gender conformity. To further test the robustness of the main results to family size (in addition to flexibly controlling for family size, as done in Column (4) in Table 3 in the main text), this subsection employs two alternative strategies: 1) dividing the sample by family size and 2) studying the effect of having a co-twin brother. Although family size is endogenous to sibling gender composition, strategy (1) is useful to the degree that it informs about the sensitivity of the results. These robustness analyses, together with the evidence of no differential effect by sibling gender on educational attainment or labor market participation [Table 5 and Figure 2] and the absence of an effect of family size on gender conformity, provide convincing evidence that family size does not confound the effects of sibling gender composition.

The first strategy is to split the sample by family size. For this, I restrict the sample to individuals who only have biological siblings, i.e. none of their parents have children with another person than the parent, although the results are similar when including those with half siblings. Given that family size is endogenous, this robustness check comes with a selection problem. If those parents of

³⁷I include all multiple births; however, twins represent the vast majority of all multiple births.

Table A3
Splitting Sample by Family Size

	Log(Male Share in Own Occ)		Share of Years in STEM Occupation		Log(Female Share in Partner's Occ)	
	(1)	(2)	(3)	(4)	(5)	(6)
Second-Born	-1.09*	-1.11	-0.49***	-0.37**	-2.26**	-1.84
Brother	(0.62)	(0.82)	(0.16)	(0.18)	(0.88)	(1.12)
Observations	58313	36010	58313	36010	53148	33331
Average	788.4	784.9	5.5	4.4	299.3	290.7
# of Siblings	1	≥ 2	1	≥ 2	1	≥ 2

All estimates are multiplied by 100 to express effects in percentage/log points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Main sample with only full siblings (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart). Each panel column presents estimates from separate regressions. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. Columns (1) through (4) also include dummies for the number of years observed in the income registry from the age of 31–40 and the number of years observed with a valid occupation code from the age of 31–40. Columns (5) and (6) also includes dummies for the partner's number of occupational observations and age at first and last observation. The occupational outcomes of the first-born women are measured as mean from the age of 31–40. The occupational outcome of the partner is measured mainly at the ages of 31–45 for the partner with whom the woman lived most years from the age of 31–41. *1 Siblings*-models restrict the sample to those who only have one full sibling and no half siblings. *≥ 2 Siblings*-models restrict the sample to those who have at least two full siblings and no half siblings.

same-sex children (born at the first two parities) who have a third child are more gender-stereotypical and influence their children’s outcomes in such a direction to a greater extent than those who do not have a third child, we would expect the effect of having a second-born brother to be stronger in magnitude among first-born children from two-child families than for the entire sample. Similarly, we would expect the effect of sibling gender to be smaller among children from families with at least three children. This is exactly what the results in Table A3 show.

Table A4
Effect of Having a Co-Twin Brother on Gender Conformity in Education

	Next Birth	Log(Male Share in Edu)	STEM Enrollment	STEM Completion
	(1)	(2)	(3)	(4)
Co-Twin Brother	-1.27* (0.73)	-4.23** (2.04)	-1.64*** (0.58)	-1.50*** (0.43)
Observations	9,380	9,357	9,380	9,380
Average	28.9	331.7	7.3	4.2

All estimates are multiplied by 100 to express effects in percentage/log points. Standard errors in parentheses, clustered at the mother level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Each column presents estimates from separate regressions. The sample comprises twins born in 1962–86. All models absorb fixed effects for birth county, year of birth, mother’s level and field of education, father’s level and field of education, parity, and age at last educational observation. The models further control for (cubed) mother’s age at birth and (cubed) father’s age at birth. *Next Birth* indicates if the parents have a subsequent child. *Log(Male Share in Edu)* measures the natural logarithm of the male share in the highest completed education (narrow field-by-level) by the age of 30. *STEM Enrollment* indicates whether the woman has ever enrolled in a field-specific STEM education at the age of 16–27. *STEM Completion* indicates whether the woman has ever completed a field-specific STEM education by the age of 30.

Finally, to circumvent potential confounding effects from family size, I examine the effect of having a co-twin brother as an alternative empirical strategy. This approach is similar to the one in Cronqvist et al. (2015) and Peter et al. (2015), except that I do not have information on zygosity. To increase power, I include birth cohorts 1962–1986 and consider the gender conformity in educational outcomes. The key empirical feature of the sample of twins is that twin gender composition only has a very limited impact on family size [Appendix Table A4, Column (1)].

Overall, the effects of having a co-twin brother on educational choice are similar to the main results. However, the magnitude of the effects are much larger. This might be due to the much greater intensity of the exposure to a co-twin compared with a younger sibling.

A.3 Educational System and Field of Study

Throughout, I follow the International Standard Classification of Education (ISCED) for the definition of all educational measures. I include observations through the age of 27 for all enrollment measures and through the age of 30 for all completion measures to give people time to complete the education in which they enroll. I define the *male share in education* as the share of men who had their highest completed education at the age of 30 within the same narrow field and level of education for cohorts born 1–5 years before the individual. The academic high school grade point average (GPA) is standardized with a mean of zero and standard deviation of one at the year of graduation and high school track level for the total population; however, note that it is only observed for those completing the academic high school.

In the final year of 9th grade, at the age of 16, students decide whether to apply for secondary education or enter the labor market.³⁸ Secondary education (ISCED level 3) comprises two types: academic high school and vocational training. The academic high school is generic (i.e. not field-specific) and prepares students for tertiary education. For the cohorts of study, the academic high school had two tracks: language and math. Vocational education is, in contrast, field-specific and prepares students for specific occupations; I group Information and Communication Technologies and Engineering (ISCED fields 61 and 71) as STEM.

Tertiary education (ISCED levels 5–8) comprises three types: vocational, professional, and academic. I refer to the latter two jointly as *college*. Similarly, I group vocational secondary and vocational tertiary educations as *vocational education*. A vocational secondary degree usually only gives direct access to vocational tertiary programs within the same specific field,³⁹ while an academic high school diploma

³⁸They can also choose to enroll in an optional 10th grade, which is a formal continuation of primary school. In the analysis, I restrict the attention to enrollment in and completion of programs after primary school, i.e. after grade 9 and 10.

³⁹Students with a vocational secondary degree will often be required to have taken one or two academic high school courses at a basic level, such as math and English. However, many vocational

gives access to all types of tertiary education. An application to tertiary education is an application to a specific program. Most college STEM programs require certain high school STEM courses as prerequisites, such as advanced math and intermediate physics and chemistry. Therefore, an academic high school STEM diploma gives much easier access to college STEM majors than other secondary school degrees, although it is possible to take complementary courses after high school graduation. Acceptance to college mainly depends on high school GPA and most STEM programs admit all eligible applicants (or have very low GPA cut-offs).

To mirror the definition of field-specific STEM education to the one of STEM occupation, I define STEM in college as Physical Sciences, Mathematics, Statistics, Economics, Information and Communication Technologies, and Engineering (ISCED fields 53, 54, 311, 61, 71). However, the results are similar when including biology. Another important reason for excluding biology is that women's underrepresentation in STEM is limited to math-intensive—and, generally, better paid—science fields (Kahn and Ginther, 2017). The analysis of STEM education considers field-specific STEM educations in any type and at any level of education after primary school. This is to not potentially confound the results on STEM choice with educational attainment. Thus, the main STEM outcomes of interest indicate whether the individual ever enrolls in and completes a field-specific STEM education preparing for the labor market, including secondary and tertiary vocational STEM programs and college STEM majors.

Moreover, I complement the main STEM measures with four additional outcomes; the results are reported in the appendix. I examine whether the first place of enrollment after primary school has a STEM focus, i.e. whether it is either secondary STEM vocational education or in the math track in the academic high school. In line with this, I consider the probability of ever completing the academic high school math track. Finally, I split field-specific STEM educations by type, thereby investigating effects on the probability of completing a vocational STEM program and a college STEM major, separately.⁴⁰

secondary programs do not have a natural continuation at the tertiary level.

⁴⁰Considering whether the highest completed education is within STEM reveals similar results as for having any field-specific STEM degree (not reported). Moreover, considering the probability of enrolling in the different types of STEM education rather than completing them also provides similar results.

A.4 Alternative Mechanisms

This appendix describes alternative mechanisms to those discussed in Subsection 5.1. However, these mechanisms cannot be the dominating ones, as they are not compatible with the empirical findings.

The effect of sibling interactions might also go in the opposite direction for two reasons. First, the spillover model in developmental psychology hypothesizes that siblings imitate and influence each other with their gender-specific traits. For instance, Brim (1958) and Koch (1955) show that mixed-sex siblings exhibit more traits of the opposite gender and fewer of their own gender compared to same-sex sibling pairs. Second, the reference group theory in sociology suggests that as soon as a same-sex sibling is present in the family, the same-sex sibling will be the child and parents' reference group (Butcher and Case, 1994). Therefore, having a same-sex sibling might induce the child to behave more gender-stereotypically. Meanwhile, given the empirical findings, neither of these two theories can be the dominating mechanism for the effect of sibling gender composition on the development of women's gender conformity.

Studies examining the relationship between sibling gender composition and educational attainment have argued that budget constraints may play an important role (Amin, 2009; Butcher and Case, 1994). If parents face no borrowing constraints, they should, according to standard economic theory, invest in each child until marginal costs equal marginal benefits. However, if parents face borrowing constraints, they might decide to allocate their financial resources depending on the gender composition of their children. If parents want income equality between their children and the returns to education are smaller for women than men, then having a brother instead of a sister would be beneficial. However, parental aversion to income inequality cannot be the dominating channel, as we would otherwise have observed that having a sibling of the opposite sex should make the educational choice less gender-stereotypical.

In contrast, parents might want to maximize the total income of their children, thereby investing more in the child with the greatest returns to education. If returns to education are higher for men than women, having a brother would have adverse effects on educational attainment. In support of this argument, Powell and Steelman (1989) find for students enrolled in one college in the U.S. that the number of brothers puts more pressure on parents' financial support than do the number of

sisters. Nevertheless, this is not a likely mechanism in the Danish context because there is no tuition fee at any educational level. Moreover, students in vocational training typically receive apprenticeship wages and students in tertiary education receive governmental student grants and loans to cover living expenses. For all cohorts in the analysis, students in tertiary education have at least had access to a combination of grants and loans of 1,000 USD a month in 2017-prices. It is also less clear how borrowing constraints should affect field choice, given sibling gender composition has no effect on the probability of enrolling in any type of program after compulsory education. Moreover, a more recent study shows that, for later generations in the U.S., parents to at least one son compared to parents with no sons do not differentially invest in their daughters (Cools and Patacchini, 2017).

A.5 Appendix Tables and Figures

Table A5
Effect of Sibling Gender on Relative Earnings and Age Difference

	(1)	(2)	(3)	(4)

Family size				✓

All estimates in Panel A are multiplied by 100 to express effects in percentage points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Main sample (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart). Each panel column presents estimates from separate regressions. *Basic controls* include fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, and paternal age at birth. For the earnings difference, basic controls also include a dummy indicating whether the woman and her partner have the same number of earnings observations. *Parental education* controls include fixed effects for maternal level-by-field of education and paternal level-by-field of education. *Family size* controls include dummies for the number of biological siblings and dummies for the number of children the mother and father potentially have, respectively, from later relationships, and the gender of potential third- and fourth-born siblings. *Relative Difference Between Partner's and Woman's Earnings* measures the difference between the partner's and the woman's labor earnings as a share of the couple's total earnings during the first five years the couple lives together when the woman is 31–40 years. *Age to Partner* measures the number of days the partner is older than the woman and is set to zero if the woman is older than the partner.

Table A6
Effect of Sibling Gender on STEM Education and Educational Performance

	STEM Focus in First En- rollment (1)	HS STEM Track Com- pletion (2)	Voca- tional STEM Com- pletion (3)	College STEM Com- pletion (4)	Grade 9 Lan- guage GPA (5)	Grade 9 Math GPA (6)

Observations	103,769	103,769	103,769	103,769	82,978	82,350
Average	22.7	18.9	2.4	2.5	44.7	22.6

All estimates are multiplied by 100 to express effects in percentage points/percent of a standard deviation. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Main sample (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart) for STEM outcomes; girls born between 1986 and 1999 with the same selection criteria as for the main sample for the grade 9 outcomes. Each column presents estimates from separate regressions. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. The STEM outcome models further control for age at last observation in the education registry. *STEM Focus in First Enrollment* indicates whether the woman's first place of enrollment after compulsory schooling is in the academic high school math track or in a field-specific vocational STEM education. *HS STEM Track Completion* indicates whether the woman has completed the academic high school math track. *Vocational STEM Completion* indicates whether the woman has completed either secondary or tertiary vocational field-specific STEM education. *College STEM Completion* indicates whether the woman has completed a college degree or higher within STEM (excluding biology). The Grade 9 GPA measures come from the written exam at the end of grade 9 in respectively Danish and Math and are standardized by year of graduation for the total population with a mean of zero and standard deviation of one.

Table A7
Principal Component Analysis: Parental Time Investment

(e) Mother's Work Experience

(f) Father Work Experience

(g) Mother's log(Earnings)

(h) Father's log(Earnings)

Sample of first-born girls born between 1985 and 2002 with a second-born biological sibling born within four years apart. The whiskers represent the 95 percent confidence interval. All graphs illustrate the estimates from an event study of the effect of having a second-born brother. All models absorb time-specific fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education.

Figure A2
Effect of Sibling Gender on Choice of Occupation and Partner:
Heterogeneity by Spacing

(a) Log(Male Share in Own Occupation)

(b) Share of Years in STEM Occupation

(c) Log(Female Share in Partner's Occupation)

Main sample (first-born women born in 1962–1975) including individuals with a second-born biological sibling born up to eight years apart. All graphs illustrate the estimated effect of having a second-born brother by birth spacing. The whiskers represent the 95 percent confidence interval. Each graph shows the estimates from a separate regression. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. The models with own occupation also include dummies for the number of years observed in the income registry from the age of 31–40 and the number of years observed with a valid occupation code from the age of 31–40. For partner's occupation, the controls also include dummies for the partner's number of occupational observations and age at first and last observation. The occupational outcomes of the first-born women are measured as mean from the age of 31–40. The occupational outcome of the partner is measured mainly at the ages of 31–45 for the partner with whom the woman lived most years from the age of 31–41.

Figure A3
Effect of Sibling Gender on Earnings at the Age of 18–40

(a) Labor Earnings

(b) Log(Earnings)

Main sample (first-born women born in 1962–1975 with a younger biological sibling born within four years apart). The whiskers represent the 95 percent confidence interval. All graphs illustrate the estimates from an event study of the effect of having a second-born brother, where the age of 18 forms the base. Both models absorb time-specific fixed effects and individual fixed effects. *Labor Earnings* is measured in 1,000 DKK 2015-prices. *Log(Earnings)* is the natural logarithm of *Labor Earnings*.

Figure A4
Distribution of Ability by Sibling Gender

(a) Academic High School GPA

(b) Grade 9 Language written exam

(c) Grade 9 Math written exam

Main sample (first-born women born in 1962–1975 with a second-born biological sibling born within four years apart) for academic high school GPA; girls born between 1986 and 1999 with the same selection criteria as for the main sample for the grade 9 outcomes. The Grade 9 GPA measures come from the written exam at the end of grade 9 in respectively Danish and Math. *Academic High School GPA* is observed for students completing the academic high school language and math tracks. The standardized GPA measures are standardized by year of graduation (for the high school GPA track-by-year of graduation) for the total population with a mean of zero and standard deviation of one. All graphs plot the distribution of the three measures of school performance by gender of the second-born sibling [sister (black) and brother (green)]. The tails are truncated to have at least five observations within each cell due to data protection rules.

Table A8
Effect of Sibling Gender on Components of Parental Time
Investment at Age 7 and 11

	Play	Home- work	Out-of- School Activ- ity	Read/ Sing	Excur- sion
	(1)	(2)	(3)	(4)	(5)
Panel A: Maternal Investment at age 7 ($N = 594$)					
Second-Born	0.10	0.09	0.01	0.04	0.14*
Brother	(0.08)	(0.08)	(0.09)	(0.08)	(0.08)
Panel B: Maternal Investment at age 11 ($N = 594$)					
Second-Born	0.15*	0.14	0.01	0.11	0.09
Brother	(0.09)	(0.09)	(0.09)	(0.09)	(0.09)
Panel C: Paternal Investment at age 7 ($N = 421$)					
Second-Born	-0.10	-0.19*	-0.01	-0.28***	-0.00
Brother	(0.10)	(0.10)	(0.10)	(0.10)	(0.10)
Panel D: Paternal Investment at age 11 ($N = 415$)					
Second-Born	-0.16	-0.22**	-0.11	-0.14	-0.08
Brother	(0.10)	(0.10)	(0.10)	(0.10)	(0.10)

Standard errors in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. DALSC sample. Each panel column represents the results from separate regressions. All models control for (quadratic) mother and father's age and fixed effects for spacing to the younger sibling in years, parental marital status in 1996, parents having been together for at least 5 years in 1996, region of birth, maternal level of education, paternal level of education, and family income level in 1995. Each of the individual components is standardized with a mean of zero and standard deviation of one.

Table A9
Effect of Sibling Gender on Quality of Child-Parent and Child-Sibling Relations

	Mother's	Father's	Child's relationship to		
	Relationship to Child	Relationship to Child	Mother	Father	Siblings
Child Age	11/15 (1)	7 (2)	15 (3)	15 (4)	15 (5)
Second-Born Brother	-0.12 (0.10)	-0.22** (0.10)	0.07 (0.09)	-0.16* (0.09)	-0.38*** (0.09)
Observations	441	434	498	489	485

Standard errors in parentheses. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. DALSC sample. Each column represents the results from separate regressions. All models control for (quadratic) mother and father's age and fixed effects for spacing to the younger sibling in years, parental marital status in 1996, parents having been together for at least 5 years in 1996, region of birth, maternal level of education, paternal level of education, and family income level in 1995. All child-parent relationship indexes represent the first component from principal component analyses, shown in Appendix Table A10, are standardized such that a higher value reflects a better relationship, the mean is zero, and the standard deviation is one. *Child's relationship to siblings* is an index of how easy the child thinks it is to talk to his/her siblings about matters that really bother her (standardized with a mean of zero and standard deviation of one).

Table A10
Principal Component Analysis: Child-Parent Relations

	Mother's	Father's	Child's rel. to	
	Rel. to Child		Mother	Father
<i>First Principal Component</i>				
Age 11: How close is the relationship between you and your daughter (1-4)?	0.71			
Age 15: How close is the relationship between you and your daughter (1-3)?	0.71			
Age 7: How close is the relationship between you and your daughter (1-4)?		0.71		
Age 7: Are you satisfied with the relationship between you and your daughter (1(yes)-2(no))?		0.71		
Age 15: Your mother/father plays a very big role in your life (1-5)			0.32	0.36
Age 15: Your relationship with your mother/father is important to you (1-5)			0.35	0.37
Age 15: Your mother/father loves you (1-5)			0.35	0.28
Age 15: You trust your mother/father (1-5)			0.38	0.40
Age 15: You can expect your mother/father to listen to you (1-5)			0.35	0.37
Age 15: You can go to your mother/father for advice (1-5)			0.40	0.36
Age 15: You can count on help from your mother/father if you have a problem (1-5)			0.36	0.37
Age 15: How easy is it to talk with your mother/father about matters that really bother you (1-5)			0.29	0.29
<i>Eigenvalue</i>				
First Component	1.34	1.25	4.07	4.53
Second Component	0.66	0.75	0.95	0.79

DALSC sample. All questions are answered on a Likert scale with lower values being better. Therefore, the standardized measures used in Table A9 are all reversed, such that a higher value reflects a better relationship.

Table A11
Association Between First-Born Sibling's Gender and Second-Born Women's Gender Conformity

	Log(Male Share in own Occ)	Works in STEM	Log(Female Share in Part- ner's Occ)	Log(Male Share in Edu)	Length (months)	High School GPA
	(1)	(2)	(3)	(4)	(5)	(6)
First-Born	-0.87*	-0.10	-1.20*	-1.15**	-0.42***	-0.05***
Brother	(0.46)	(0.11)	(0.67)	(0.52)	(0.15)	(0.01)
Observations	105,445	105,445	95,598	105,171	105,189	41,414
Average	787.6	4.623	292.2	333.6	156.9	0.002

Sample of second-born women born in 1962–1975 with a first-born biological sibling born within four years apart. Each column presents estimates from separate regressions. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to older sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. For the own occupation outcomes, controls also include dummies for the number of years observed in the income registry from the age of 31–40 and the number of years observed with a valid occupation code from the age of 31–40. For partner's occupation, controls also include dummies for the partner's number of occupational observations and age at first and last observation. The educational outcome models, except for high school GPA, further control for age at last observation in the education registry. The occupational outcomes of the second-born women are measured as mean from the age of 31–40. The occupational outcome of the partner is measured mainly at the ages of 31–45 for the partner with whom the woman lived for most years from the age of 31–41. *Log(Male Share in Edu)* measures the natural logarithm of the share of men in the highest completed education (narrow field-by-level) by the age of 30. *Length* measures the length of the highest completed education in months by the age of 30. *HS GPA* measures final GPA from the academic high school and is standardized by track and year of graduation for the total population with a mean of zero and standard deviation of one.

Table A12
Men: Effect of Sibling Gender on Choice of Occupation

	(1)	(2)	(3)	(4)
Panel A: Log(Male Share in Own Occupation)				
Second-Born	0.51**	0.48*	0.44*	0.52**
Sister	(0.26)	(0.25)	(0.25)	(0.25)
Observations	108,366	108,365	108,365	108,365
Panel B: Share of Years Working in STEM Occupation				
Second-Born	0.44**	0.48***	0.51***	0.47***
Sister	(0.18)	(0.18)	(0.18)	(0.18)
Observations	108,366	108,365	108,365	108,365
Panel C: Share of Years Working as Manager				
Second-Born	-0.46***	-0.45***	-0.44***	-0.44***
Sister	(0.12)	(0.12)	(0.11)	(0.12)
Observations	108,366	108,365	108,365	108,365
No controls	✓			
Basic controls		✓	✓	✓
Parental education			✓	✓
Family size				✓

All estimates are multiplied by 100 to express effects in percentage/log points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Male main sample (first-born *men* born in 1962–1975 with a second-born biological sibling born within four years apart). Each panel column presents estimates from separate regressions. *Basic controls* include fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, number of years observed in the income registry from the age of 31–40, and the number of years observed with a valid occupation code from the age of 31–40. *Parental education* controls include fixed effects for maternal level-by-field of education and paternal level-by-field of education. *Family size* controls include dummies for the number of biological siblings and dummies for the number of children the mother and father potentially have, respectively, from later relationships, and the gender of potential third- and fourth-born siblings. The outcomes are measured as mean from the age of 31–40.

Figure A5

Men: Effect of Sibling Gender on Labor Market Outcomes at the Age of 18–40

(a) Earnings Percentile

(b) Cumulated Work Experience

(c) Cumulated Unemployment

Male main sample (first-born *men* born in 1962–1975 with a younger biological sibling born within four years apart). The whiskers represent the 95 percent confidence interval. All graphs illustrate the estimates from an event study of the effect of having a second-born brother, where the age of 18 forms the base. All models absorb time-specific fixed effects and individual fixed effects. *Earnings Percentile* measures the labor earnings percentile by age and cohort. *Work Experience* measures the cumulated lifetime work experience in months. *Unemployment* measures the cumulated lifetime unemployment in months.

Table A13
Men: Effect of Sibling Gender on Education and Family Formation

	(1)	(2)	(3)	(4)	(5)
Panel A: Education by age 30					
	Log(Male Share)	Length (months)	High School GPA	STEM Enrollment	STEM Completion
Second-Born Sister	0.47 (0.29)	-0.06 (0.15)	0.01 (0.01)	1.16*** (0.30)	0.45 (0.28)
Observations	107,898	107,921	31,973	108,365	108,365
Panel B: Family Formation by the Age of 41					
	Cohabit 18–41	Married 18–41	Has Any Children	# of Children	Age at First Birth
Second-Born Sister	-0.39*** (0.12)	-0.88*** (0.15)	-1.56*** (0.24)	-0.04*** (0.01)	0.09*** (0.03)
Observations	108,365	108,365	108,365	108,365	86,124

Estimates in Columns (1), (4), and (5) in Panel A and Columns (1), (2), and (3) in Panel B are multiplied by 100 to express effects in percentage/log points. Standard errors in parentheses; * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. Male main sample (first-born *men* born in 1962–1975 with a second-born biological sibling born within four years apart). Each panel column presents estimates from separate regressions. All models absorb fixed effects for birth municipality, year-by-month of birth, spacing in months to younger sibling, maternal age at birth, paternal age at birth, maternal level-by-field of education, and paternal level-by-field of education. The educational outcome models (except for high school GPA), further control for age at last observation in the education registry. *Log(Male Share)* measures the natural logarithm of the share of men in the highest completed education (narrow field-by-level) by the age of 30. *Length* measures the length of the highest completed education in months by the age of 30. *High School GPA* measures final GPA from the academic high school and is standardized by track and year of graduation for the total population with a mean of zero and standard deviation of one. *STEM Enrollment* indicates whether the man has ever enrolled in a field-specific STEM education at the age of 16–27. *STEM Completion* indicates whether the man has ever completed a field-specific STEM education by the age of 30. *Cohabit* measures the share of years aged 18–41 during which the man has cohabited with a partner without being married. *Married* measures the share of years aged 18–41 during which the man has been married. *Has Any Children* indicates whether the man has at least one child by the age of 41. *# of Children* measures the number of children the man has by the age of 41. *Age at First Childbirth* measures the age at the man’s first child birth in years, conditional on having any children.
